9. Operations with Pandas objects

```
In [1]: import pandas as pd import numpy as np
```

One of the great advantages of using Pandas to handle tabular data is how simple it is to extract valuable information from them. Here we are going to see various types of operations that are available for this.

9.1 Matrix types of operations

The strength of Numpy is its natural way of handling matrix operations, and Pandas reuses a lot of these features. For example one can use simple mathematical operations to operate at the cell level:

```
In [2]:
         compo_pd = pd.read_excel('Data/composers.xlsx')
         compo_pd
Out[2]:
              composer birth death
                                            city
          0
                 Mahler
                        1860
                              1911
                                          Kaliste
          1
              Beethoven 1770
                              1827
                                           Bonn
                 Puccini 1858
          2
                              1924
                                         Lucques
            Shostakovich 1906
                              1975 Saint-Petersburg
         compo_pd['birth']*2
In [3]:
Out[3]: 0
               3720
               3540
         1
         2
               3716
         3
               3812
         Name: birth, dtype: int64
In [4]: | np.log(compo_pd['birth'])
Out[4]:
         0
               7.528332
               7.478735
               7.527256
         2
               7.552762
         Name: birth, dtype: float64
```

Here we applied functions only to series. Indeed, since our Dataframe contains e.g. strings, no operation can be done on it:

```
In [5]: #compo_pd+1
```

If however we have a homogenous Dataframe, this is possible:

```
In [6]:
         compo_pd[['birth','death']]
Out[6]:
             birth death
             1860
                   1911
                   1827
            1770
             1858
                   1924
            1906
                   1975
         compo pd[['birth','death']]*2
Out[7]:
             birth death
                   3822
             3720
            3540
                   3654
            3716
                   3848
            3812
                   3950
```

9.2 Column operations

There are other types of functions whose purpose is to summarize the data. For example the mean or standard deviation. Pandas by default applies such functions column-wise and returns a series containing e.g. the mean of each column:

Note that columns for which a mean does not make sense, like the city are discarded. A series of common functions like mean or standard deviation are directly implemented as methods and can be accessed in the alternative form:

```
compo pd.describe()
 In [9]:
 Out[9]:
                        birth
                                   death
            count
                     4.000000
                                4.000000
                 1848.500000
                             1909.250000
            mean
                    56.836021
                               61.396933
             std
             min 1770.000000
                             1827.000000
                  1836.000000
                             1890.000000
             50%
                  1859.000000
                             1917.500000
                 1871.500000 1936.750000
             max 1906.000000 1975.000000
In [10]: compo pd.std()
Out[10]: birth
                     56.836021
           death
                     61.396933
           dtype: float64
```

If you need the mean of only a single column you can of course chains operations:

```
In [11]: compo_pd.birth.mean()
Out[11]: 1848.5
```

9.3 Operations between Series

We can also do computations with multiple series as we would do with Numpy arrays:

We can even use the result of this computation to create a new column in our Dataframe:

```
In [13]:
           compo pd
Out[13]:
                 composer birth
                                 death
                                                  city
            0
                    Mahler
                           1860
                                  1911
                                               Kaliste
            1
                 Beethoven
                           1770
                                  1827
                                                 Bonn
            2
                    Puccini 1858
                                  1924
                                              Lucques
            3 Shostakovich 1906
                                  1975 Saint-Petersburg
In [14]:
           compo_pd['age'] = compo_pd['death']-compo_pd['birth']
           compo_pd
In [15]:
Out[15]:
                 composer birth
                                 death
                                                  city
                                                      age
            0
                    Mahler
                           1860
                                  1911
                                               Kaliste
                 Beethoven
                           1770
                                  1827
                                                 Bonn
                                                        57
            2
                   Puccini 1858
                                  1924
                                              Lucques
                                                        66
              Shostakovich 1906
                                  1975 Saint-Petersburg
```

9.4 Other functions

Sometimes one needs to apply to a column a very specific function that is not provided by default. In that case we can use one of the different apply methods of Pandas.

The simplest case is to apply a function to a column, or Series of a DataFrame. Let's say for example that we want to define the the age >60 as 'old' and <60 as 'young'. We can define the following general function:

```
In [16]: def define_age(x):
    if x>60:
        return 'old'
    else:
        return 'young'

In [17]: define_age(30)
Out[17]: 'young'
In [18]: define_age(70)
```

We can now apply this function on an entire Series:

```
In [19]: compo_pd.age.apply(define_age)
Out[19]: 0
               young
         1
               young
         2
                 old
         3
                 old
         Name: age, dtype: object
In [20]: compo_pd.age.apply(lambda x: x**2)
Out[20]:
         0
               2601
               3249
         1
               4356
         3
               4761
         Name: age, dtype: int64
```

And again, if we want, we can directly use this output to create a new column:

```
compo pd['age def'] = compo pd.age.apply(define age)
In [21]:
           compo pd
Out[21]:
                 composer birth death
                                                 city age age_def
            0
                           1860
                                 1911
                                               Kaliste
                    Mahler
                                                       51
                                                             young
            1
                 Beethoven 1770
                                 1827
                                                Bonn
                                                       57
                                                             young
            2
                   Puccini 1858
                                 1924
                                             Lucques
                                                       66
                                                               old
            3 Shostakovich 1906
                                 1975 Saint-Petersburg
                                                       69
                                                               old
```

We can also apply a function to an entire DataFrame. For example we can ask how many composers have birth and death dates within the XIXth century:

```
In [22]: def nineteen_century_count(x):
    return np.sum((x>=1800)&(x<1900))

In [23]: compo_pd[['birth','death']].apply(nineteen_century_count)

Out[23]: birth    2
    death    1
    dtype: int64</pre>
```

The function is applied column-wise and returns a single number for each in the form of a series.

Here the operation is again applied column-wise but the output is a Series.

There are more combinations of what can be the in- and output of the apply function and in what order (column- or row-wise) they are applied that cannot be covered here.

9.5 Logical indexing

Just like with Numpy, it is possible to subselect parts of a Dataframe using logical indexing. Let's have a look again at an example:

```
In [26]:
            compo_pd
Out[26]:
                  composer birth
                                  death
                                                    city
                                                              age_def
                                                         age
             0
                     Mahler
                                                  Kaliste
                                                                 young
             1
                  Beethoven
                            1770
                                    1827
                                                   Bonn
                                                           57
                                                                 young
             2
                     Puccini
                            1858
                                    1924
                                                 Lucques
                                                           66
                                                                   old
               Shostakovich 1906
                                    1975 Saint-Petersburg
                                                           69
                                                                   old
```

If we use a logical comparison on a series, this yields a logical Series:

```
compo_pd['birth']
In [27]:
Out[27]:
        0
               1860
         1
               1770
         2
               1858
               1906
         3
         Name: birth, dtype: int64
In [28]:
         compo_pd['birth'] > 1859
Out[28]:
         0
                True
               False
               False
                True
         Name: birth, dtype: bool
```

Just like in Numpy we can use this logical Series as an index to select elements in the Dataframe:

```
In [29]: log indexer = compo pd['birth'] > 1859
           log_indexer
Out[29]:
          0
                 True
                False
           2
                False
           3
                 True
           Name: birth, dtype: bool
In [30]:
           compo pd
Out[30]:
                composer birth death
                                               city age age_def
           0
                   Mahler
                         1860
                                1911
                                             Kaliste
                                                    51
                                                          young
           1
                Beethoven
                         1770
                                1827
                                              Bonn

           2
                  Puccini
                         1858
                                1924
                                            Lucques
                                                    66
                                                            old
           3 Shostakovich 1906
                                1975 Saint-Petersburg
                                                    69
                                                            old
In [31]: ~log_indexer
Out[31]: 0
                False
                  True
           2
                 True
           3
                False
           Name: birth, dtype: bool
In [32]:
          compo pd[~log indexer]
Out[32]:
              composer birth death
                                       city age
                                                age_def
              Beethoven
                                      Bonn
                                                  young
           2
                 Puccini
                       1858
                              1924 Lucques
                                            66
                                                    old
```

We can also create more complex logical indexings:

```
In [33]:
          (compo_pd['birth'] > 1859)&(compo_pd['age']>60)
Out[33]: 0
               False
          1
               False
          2
               False
                True
          dtype: bool
In [34]:
          compo pd[(compo pd['birth'] > 1859)&(compo pd['age']>60)]
Out[34]:
               composer birth death
                                            city
                                                    age_def
                                               age
          3 Shostakovich 1906
                              1975 Saint-Petersburg
```

And we can create new arrays containing only these subselections:

```
In [35]: compos_sub = compo_pd[compo_pd['birth'] > 1859]
```

```
In [36]:
            compos sub
Out[361:
                  composer
                             birth
                                   death
                                                     city
                                                          age
                                                               age_def
                     Mahler
                             1860
                                    1911
                                                  Kaliste
                                                                 young
             3 Shostakovich 1906
                                    1975 Saint-Petersburg
                                                           69
                                                                   old
```

We can then modify the new array:

3 Shostakovich 1906

```
In [37]: compos_sub.loc[0,'birth'] = 3000
```

/Users/gw18g940/miniconda3/envs/danalytics/lib/python3.8/site-packages/pandas/core/indexing.py:966: SettingWithCopyWarning:
A value is trying to be set on a copy of a slice from a DataFrame.
Try using .loc[row indexer,col indexer] = value instead

See the caveats in the documentation: https://pandas.pydata.org/pandas-docs/stable/user_guide/indexing.html#returning-a-view-versus-a-copy self.obj[item] = s

Note that we get this SettingWithCopyWarning warning. This is a very common problem hand has to do with how new arrays are created when making subselections. Simply stated, did we create an entirely new array or a "view" of the old one? This will be very case-dependent and to avoid this, if we want to create a new array we can just enforce it using the copy() method (for more information on the topic see for example this explanation (https://www.dataquest.io (blog/settingwithcopywarning/):

```
In [38]:
          compos_sub2 = compo_pd[compo_pd['birth'] > 1859].copy()
           compos sub2.loc[0, 'birth'] = 3000
In [39]:
          compos_sub2
Out[391:
               composer
                         birth
                              death
                                              city
                                                  age
                                                      age_def
           0
                  Mahler
                         3000
                               1911
                                            Kaliste
                                                   51
                                                        young
```
